Abstract

A 1:6,250 map of the foreland of Fláajökull's north lobe as it appeared in 1989, together with a 1:350 scale map of a sample area of recently exposed glacial landforms from 2014, enables an assessment of the spatial and temporal evolution of glacial landform assemblages at the margin of an active temperate piedmont lobe terminating at ice-marginal thickening till wedges. The pattern of landform development captured in these maps indicates that the glacier margin developed strong longitudinal crevassing and well-developed ice-marginal pecten (three dimensional crenulations) during its historical recession. This is recorded by early recessional phase linear push moraines on well-drained distal slopes of the foreland and the later development of inter-related sawtooth moraines, crevasse squeeze ridges and till eskers, indicative of extending ice flow and poorly drained sub-marginal conditions. This landform record is a palaeoglaciological signature of a changing process-form regime inherent within the active temperate piedmont lobe landsystem model.

Key words: glacial landsystem; active temperate glacier; Iceland

1. Introduction

The aim of this study was to map, at the large scale of 1:6,250, the distribution of glacial sediment-landform associations on the Fláajökull north lobe foreland (Figure 1), an area that displays a conspicuous arcuate moraine assemblage, comprising fluted/overridden ridges, recessional push ridges and geometrical ridge networks. This landsystem signature displays many similarities to that of the neighbouring forelands of Heinabergsjökull and Skálafellsjökull (Evans & Orton 2014), indicative of all these glacier snouts being characterized by the dynamics of active temperate piedmont lobes. However, the density of overridden moraines and widespread occurrence of sawtooth moraines (cf. Price 1970; Matthews et al. 1979; Fredin & Burki 2008; Burki et al. 2009) with unusually long limbs, geometrical ridges (crevasse infills), and numerous till eskers (*sensu* Christoffersen et al. 2005; Larsen et al. 2006; Evans et al. 2010) are embellishments specific to this landsystem that reflect the intensive development of longitudinal crevassing in lobate snouts terminating at marginal-thickening till wedges (cf. Evans & Hiemstra 2005) rather than outwash heads, as exemplified at Heinabergsjökull. Given the importance of the juxtaposition and complex interactions of the various sub-marginal landforms evolving at the glacier snout at the present day, a further larger scale map (1:350) was produced for a small area of the foreland based upon an unmanned aerial vehicle (UAV) aerial survey in 2014. This large scale mapping provides some details

39 representative of the complex set of landforms that have emerged on the foreland since 1989,
40 during which time Fláajökull has receded by more than 500 m

41

42 **2. Methods of map production**

43 The map 1:6,250 map has been produced with no new topographical ground survey of the study
44 area. Hence the landform and surficial geology mapping was undertaken on two, non-rectified, and
45 manually stitched aerial photographs taken by Landmælingar Íslands in 1989, and contours are
46 derived from the existing 1:50,000 topographic map, based on the ISN 93 datum. The relief of most
47 landforms is less than the 20 m contour intervals and therefore the lack of newly surveyed contours
48 does not impact significantly on the representation of the glacial geomorphology. The distortion
49 inherent in non-rectified aerial photographs was minimized by using the central portions of the
50 images for mapping. The glacier surface is represented by a mask compiled directly from the aerial
51 photographs but does not contain any contours as these were not surveyed for this map.

52

53 Since 1989 Fláajökull has receded by more than 500 m along most of its margin, exposing a complex
54 network of glacial landforms. Continued observations on the spatial and temporal development of
55 these landforms provide invaluable insights into the evolution of the glacial geomorphology of the
56 whole foreland and hence a large scale (1: 350) map of the most recent features exposed at the
57 north side of the snout was compiled based on a UAV survey in September 2014 (Figure 2). Low
58 altitude images were taken using a small, lightweight UAV quadcopter equipped with a 12-
59 megapixel, wide-angle lens camera. Images were acquired at an elevation of 40 m above the
60 launching point. The ground image pixel size was ~0.016 m. In total four flights were performed and
61 175 images were taken covering 0.1 km². The craft was equipped with a 3D gimbal system and
62 because images were acquired while the craft was hovering, photographs were all well focussed.
63 The images were handled with Agisoft Photoscan software. A point-cloud containing 98.90 million
64 points was generated and subsequently georeferenced to the UTM 28N coordinate system using 23
65 ground control points (GCPs). GCPs were surveyed with Topcon Hiper II dGPS system and post-
66 processed. GCPs were used to optimize and provide survey control on the point-cloud. An average
67 density of points was 963.7 points/m². Finally, meshed 3D models were generated from the point-
68 cloud and subsequently transformed into a raster, grid DEM with 0.03 m cell size. The total DEM
69 error measured against GCPs was 0.063 m (x = 0.037, y = 0.038, z = 0.035). A low-density point-cloud
70 was used to produce an orthophoto mosaic with the 0.016 m cell size to enable high resolution
71 landform mapping.

72

3. Historical evolution of the Fláajökull snout and foreland

The earliest map of Fláajökull is the Danish Geodetic Survey map of 1904, which depicts the glacier margin some 300 m inside the maximum historical limit (Figure 1). Evans et al. (1999) lichenometrically dated the outermost moraine of Fláajökull's south lobe, in the valley (Heinar) that joins the foreland of Heinabergsjökull. From this they proposed an age of 1884/85 based upon the age-size approach and an acceptance of historical documentation that indicates an 1887 AD maximum age for the outermost Little Ice Age moraines in the area, for both Heinabergsjökull and Fláajökull (Thorarinsson 1939); the period 1882-1892 was identified by Ahlmann and Thorarinsson (1937) as a time frame for the maximum of the most recent Little Ice Age advance of Fláajökull. A longer chronology has been proposed by McKinzeý et al. (2004, 2005) for the Heinabergsjökull moraines lying immediately inside the proposed 1887 AD moraines of Evans et al. (1999). This is based upon the employment of the size-frequency lichenometric method and the discovery of tephras in the moraine stratigraphy, suggesting a date of sometime between 1850 and 1887 AD, using Bradwell's (2004) age-gradient curve, or 1818–1886 AD, using Bradwell's (2001) age-size curve. These calculations infer an older age for Evans et al.' (1999) outer moraine, a moraine that Dabski (2002, 2007) suggests dates to 1870-1894 AD using a variety of dating methods and archives.

In the early to mid-1990s, a number of south Vatnajökull outlet glaciers, including Fláajökull, readvanced and maintained a quasi-stationary ice front for around 5 years (cf. Bradwell et al. 2006; Evans et al. 2009; Bennett & Evans 2012). This was significant in terms of the Fláajökull foreland geomorphology in that it resulted in the construction of a composite push moraine (Evans 2003, 2005; Evans & Hiemstra 2005) typical of stationary temperate glacier snouts (Krüger 1993; Evans 2013). This moraine was being initiated at the time of aerial photograph capture in 1989 and was observed during its construction and abandonment over the period 1993-2002, allowing a full understanding of the process-form relationships and process sedimentology associated with sub-marginal till accretion and moraine genesis (Evans & Hiemstra 2005).

The large lakes that are portrayed on the map near the snout have been deepened and extended by the artificial damming of the westerly flowing meltwater rivers as part of a long term strategy to divert the proglacial drainage over the sandur (see "made ground" surficial geology classification). More recently, further dams have been constructed to divert the majority of the drainage again towards the west, resulting in the more extensive flooding of the landforms portrayed on this map around the large lakes and in the linear sandur corridors that are aligned ice margin parallel.

105 **4. Glacial geomorphology and surficial geology**

106 Seven surficial geology map units are identified on the glacier foreland on the 1:6,250 scale map,
107 each one being associated with specific landforms and geomorphic process-form regimes. These are
108 colour-coded on the map and relevant landforms are depicted using symbology, following the
109 protocol established for previous Icelandic glacier foreland maps (Bennett et al. 2010; Evans & Twigg
110 2002; Evans et al. 2006a, 2007, 2009; Evans & Orton 2014; Howarth & Welch 1969a, 1969b). The
111 foreland is dominated by glacialfluvial deposits and till, with other surficial units forming only minor
112 coverage.

114 **4.1 Till and moraine**

115 The till and moraines surficial map unit is characterized by the surface flutings and recessional push
116 moraines typical of the active temperate landsystems of southern Iceland but also contains
117 conspicuous crevasse fill ridges and minor till eskers, that are not widely displayed in active
118 temperate forelands elsewhere. Individual till stratigraphic units are typically less than 1 m thick and
119 display all the characteristics of subglacial traction till (Evans 2000; Evans et al. 2006b). Thicker till
120 coverage occurs where composite moraines have been constructed by marginal till wedge stacking,
121 resulting in repeating vertical sequences of multiple A and B horizons (*sensu* Boulton & Hindmarsh
122 1987; Figure 3). Such a process was observed during the early 1990s, when a negative North Atlantic
123 Oscillation signal triggered glacier snout readvance and stabilization for at least 5 years (Bradwell et
124 al. 2006; Evans & Hiemstra 2005; Figure 4a, b). The resulting composite moraine (Figure 4c) was
125 under construction on the 1989 aerial photographs and hence is depicted in this map at the glacier
126 margin. Thicker tills also occur where the most recent (historical Little Ice Age) till sheet overlies
127 overridden moraines. More common are thin tills (<1 m thick) and individual recessional push
128 moraines, which are produced every year and typically have a saw-tooth or crenulated plan form
129 (Figure 5). This morphology has been clearly related in Iceland to construction along glacier snouts
130 strongly indented by closely spaced, longitudinal crevasses or pecten (Price 1970; Sharp 1984; Evans
131 & Twigg 2002; Evans & Orton 2014). The localized close spacing of these moraines, together with
132 annual shifts in the positioning of pecten, gives rise to areas of extremely complex superimposition
133 (Figure 5). Although the fine-grained diamictic till blanket and sawtooth push moraines dominate the
134 till and moraine map unit, more bouldery tills and moraines have been constructed at the former
135 southwest margin of the glacier (Figure 6). Here a sequence of marginally stacked boulder-rich tills
136 have been constructed at the historical Little Ice Age maximum limit, documenting the delivery of
137 coarser debris loads to the former ice margin from the steep bedrock bluffs that separate the north
138 and south lobes of Fláajökull.

139

140 The locally well-developed crevasse fill ridges and minor till eskers are morphologically distinct from
141 push moraines because they are orientated oblique to push moraine crests but not parallel to
142 former ice flow, the latter indicated by adjacent fluting patterns. The crevasse fill ridges are similar
143 to the geometric ridge networks described from many other glacier forelands (cf. Sharp 1985; Evans
144 & Rea 1999, 2003; Jónsson et al. 2014) in that they comprise numerous straight limbs attached end
145 on end, and in places cross each other to form elongate rectilinear nets. However, they nowhere
146 resemble the dense, polygonal net shapes that have been reported as evidence of surge-induced
147 crevasse squeeze ridge construction in Iceland (Sharp 1985; Evans & Rea 1999; Kjær et al. 2008; Rea
148 & Evans 2011; Schomacker et al. 2014). In a number of cases these ridges merge into, or are aligned
149 with, the limbs of sawtooth moraines, indicating that they originated by a similar depositional
150 mechanism. Many such examples are now visible on the recently (post 1990s) deglaciated foreland
151 (Figure 7), some of which are difficult to distinguish from flutings because they have been squeezed
152 up into very long longitudinal crevasses. Hence the Fláajökull crevasse fill ridges are a product of
153 glacier sub-marginal till squeezing into the dense longitudinal crevasse networks that give rise to
154 remarkably indented radial pecten at the snout. Therefore the sawtooth push moraines and
155 crevasse fill ridges are a landform assemblage diagnostic of strong radial ice flow in piedmont lobes
156 overlying deforming till in saturated (poorly drained) locations (cf. Jónsson et al. 2014). Their
157 predominance on the tops of overridden moraine arcs on only the inner half of the foreland attests
158 to the former extensional crevassing created in the ice margin by the localized, arcuate topographic
159 high points in the glacier bed.

160

161 Sinuous diamicton ridges or till eskers (Figure 8) have been identified previously on only a few glacier
162 snouts globally (cf. Christoffersen et al. 2005; Larsen et al. 2006; Evans et al. 2010). Their origin in
163 Icelandic settings is hypothesized to relate to the squeezing of dilatant till into an elongated cavity or
164 R-channel immediately after meltwater evacuation, during a short period when the pressure
165 gradient between the cavity and the till bed was steep and hence saturated till was subject to
166 localized creep towards the elongate low pressure zone (Evans et al. 2010). In order to be preserved
167 on a deglaciated foreland, till eskers must have been produced during the final stages of subglacial
168 sedimentation, otherwise shear deformation would have remoulded them. As crevasse squeeze
169 ridge preservation requires the same conditions, it is unsurprising to find them juxtaposed with till
170 eskers (Figure 9).

Previous maps of the forelands of Icelandic active temperate glaciers have depicted areas of discrete overridden moraines but the extensive nature of the overridden moraine arcs at Fláajökull necessitate their inclusion in the till and moraine mapping unit. They constitute the underlying topography of the till and moraine area but are most prominent in the middle and inner foreland where they give rise to enclosed contours at 40 m and 60 m above sea level (Figure 10). They are inset, low amplitude arcs of fluted till (cf. Evans et al. 1999, 2009; Evans & Orton 2014; Evans & Twigg 2002; Krúger 1994) deposited prior to or during glacier advance to the historical Little Ice Age limit and then superimposed by sharper relief recessional push moraines during snout recession. The crests of the more recent push moraines are predominantly orientated parallel with the summit crests of the overridden moraines, making them easy to distinguish from other adornments including crevasse fill ridges and till eskers. Areas dominated by overridden moraines are evident also on the map where elongate ponds are absent or rare; such ponds are common between the localized high points formed by the recessional push moraines, especially on the outer foreland where overridden moraine arcs are less prominent.

4.2 Glacifluvial deposits

Glacifluvial deposits (including sand and gravel-cored eskers) are predominantly located in proglacial outwash sandur fans and glacier-margin parallel linear sandar. The major terraces and eroded cliffs on the sandar are mapped by the identification of terrace and cliff edges. The sandur fans, occupying the southwest, south and east parts of the map, were constructed largely during the historical Little Ice Age maximum when proglacial streams drained the outermost moraine arc. These have been incised and are now only partially occupied by the modern drainage after it passes through corridors between the overridden moraine arcs. Recent attempts by farmers to modify the drainage have given rise to localized ponding of these drainage corridors. The corridors are occupied by linear sandar which are orientated parallel to the ice-margin because they have been and are directed by the underlying topography of the overridden moraine arcs (Figure 10). Sand and gravel cored eskers are rare on the foreland, being located only in a large melt-out depression on the north side of the snout. This depression and its associated landforms, including the eskers, has evolved and gradually drained over the last two decades. The evolution of the area from a largely flat but locally pitted outwash surface to a large depression containing gravel and sand mounds and esker ridges displays all the process-form relationships of areas of melting glacier snouts buried by glacifluvial outwash and containing englacial drainage tunnels. Similar landform assemblages have evolved at the margins of Breiðamerkurjökull (Evans & Twigg 2002), Kvíárjökull (Bennett et al. 2010; Bennett &

Evans 2012) and Virkisjökull/Falljökull (Livingstone et al. 2010; Bradwell et al. 2013), where meltwater drainage appears to have bypassed overdeepenings in the subglacial environment.

4.3 *Glacilacustrine deposits*

A minor pocket of glacilacustrine deposits occurs on the northern part of the foreland, where it records the gradual emptying of the large melt-out depression produced by burying of part of the glacier snout by glacifluvial outwash. This forms a thin blanket to a veneer generally less than 3 m thick of sands, silts and clays.

4.4 *Bedrock, residuum and paraglacial deposits*

Minor surficial units of bedrock, residuum and paraglacial deposits are depicted at the western and northern extremities of the map where they occur in association with the steep mountain slopes of Jökulfell and Fláfjall respectively. The *in situ* weathering products of the bedrock, which occur on the more shallow slopes and knolls, are classified as residuum. These areas of weathered bedrock also contain small patches of deeply weathered or wind deflated pre-Little Ice Age till too small to depict at this scale. Also present in such areas are localized drapes of aeolian (tephra) deposits and peat, especially in topographic hollows, again too small for representation at this scale. The paraglacial deposits include colluvial and debris flow fed fans reworked since historical glacier recession from glacial deposits on steeper slopes. Also included as paraglacial materials are scree slopes and debris flow fans derived from mechanically weathered bedrock outcrops. Numerous small bedrock outcrops, too small to map at this scale, also occur within the areas mapped as paraglacial deposits.

4.5 *Made ground*

Due to the localized historical modification of the foreland by farmers attempting to divert glacial meltwater, there are small areas of made ground. These constitute dams which have also been used as tracks and occur only in the western part of the foreland.

Spatial and temporal changes in the Fláajökull foreland: implications for the active temperate glacial landsystem model

Glacial landsystem maps allow the identification of landform patterns which can be instructive in relating process to form in both a spatial and temporal framework (cf. Bennett et al. 2010; Evans & Twigg 2002;). At Fláajökull, the north lobe has produced a distinct set of landform patterns that can be related to changing glaciological conditions through time and hence allow us to refine the active temperate piedmont lobe landsystem model (Figure 11). Firstly, we interpret the multiple arcs of overridden moraines as products of composite push ridge construction during phases of glacier

239 stillstand (cf. Evans & Hiemstra 2005), either during a previous period of snout recession or during its
240 advance to the Little Ice Age maximum. The marked snout-parallel linearity of the sandar deposited
241 since recession from the Little Ice Age maximum limit has been developed as a result of the
242 topographic control exerted by the overridden moraine arcs. Secondly, the recessional push
243 moraines display two clear patterns; closely spaced and more linear forms occur on the outer
244 foreland, whereas more sawtooth and partially superimposed forms occur on the inner foreland.
245 The moraines of the inner foreland are also arranged in a series of clusters, the spacing between
246 each cluster getting progressively smaller towards the present glacier margin. These two zones are
247 separated by a fluted till surface with very few, fragmented push moraines, recording a period of
248 glacier retreat over a distance of 250 m when moraine construction was subdued, likely due to rapid
249 snout recession. Prior to and after this, more substantial push moraines were constructed every 2-50
250 m, with some superimposed moraines indicating several or more years of ice marginal stillstand.
251 Finally, the distribution of crevasse squeeze ridges and till eskers on the inner foreland indicates that
252 sub-marginal conditions were conducive to the squeezing of till into full depth crevasses and tunnels
253 in the snout during the more recent period of glacier recession. This coincides with the change in
254 push moraine pattern identified above and therefore represents a geomorphic signature of a change
255 from a non-crevassed to a longitudinally crevassed snout with well-developed pecten as well as a
256 change from a well-drained to poorly-drained foreland.

257 The underlying control on both of these inter-related changes is the topography of the substrate
258 that was inherited by the glacier snout as it advanced and retreated from its historical Little Ice Age
259 maximum. Specifically this topography was the surface of the overridden moraine arcs, as defined by
260 the enclosed 40 m and 60 m contours; these contours define two overridden moraine arcs, the
261 outermost of which possesses a long, shallow distal slope on which the outer zone of linear
262 recessional push moraines and flutings are developed. The inner zone of superimposed sawtooth
263 moraines, crevasse squeeze ridges and till eskers are developed inside the steeper, proximal slope of
264 the outer overridden moraine arc; the increased spacing density of the sawtooth moraines begins
265 inside the innermost overridden moraine arc where more extensive areas of low lying, poorly
266 drained surfaces occur. Since 1989, when the aerial photographs used for mapping were taken,
267 another overridden moraine arc has emerged, as represented by the enclosed 60 m contours on the
268 northeast side of snout; this topographic high point has been adorned with the composite push
269 moraine constructed during the mid-1990s readvance (Figure 5). Hence the glacial geomorphology
270 records the development of strong longitudinal crevassing and concomitant well-developed ice-
271 marginal pecten in the north lobe during its historical recession (Figure 9); during early recession
272 from the shallow distal slope of the outermost overridden moraine, ice flow was most likely

compressive and hence the ice margin was not heavily crevassed. Drainage was also unimpeded towards the south and onto the proglacial sandur fan. In contrast, since recession from the steeper proximal slope of the outermost overridden moraine arc, ice flow has been extensional as well as strongly lobate and the glacier snout has progressively thinned. Therefore full depth crevassing and pecten production has been the dominant control on glacier sub-marginal and marginal landform construction. Combined with the relatively poor proglacial drainage imparted by the emerging subglacial topography, this has given rise to a clear change in the nature and distribution of glacial landforms on the foreland and hence a palaeoglaciological signature of a changing process-form regime in an active temperate glacier lobe fed by marginal-thickening till wedges.

Conclusion

The 1:6,250 scale map of the glacial geomorphology and surficial geology of the Fláajökull north lobe foreland depicts an arcuate moraine assemblage, composed of fluted and overridden moraines superimposed by smaller recessional push moraines, geometrical ridge networks (crevasse squeeze ridges) and till eskers. The overridden moraines contain cores of multiple tills and associated glaci-fluvial sediments and mark the locations of former composite push moraine construction by glacier-marginal till thickening during periods of glacier stillstand, similar to that observed during the mid-1990s. They were overridden and fluted by the glacier during its advance to the Little Ice Age maximum and, despite being superimposed by smaller scale recessional landforms, their morphology has exerted a topographic control on the routing of proglacial outwash in snout-parallel linear sandar tracts. This subglacial topography, comprising three inset overridden moraine arcs lying inside a shallow distal sloping foreland, has been influential also in changing the glaciological and sub-marginal drainage conditions through time, as documented by the nature and pattern of the superimposed landforms that document the historical recession of the snout. The landforms indicate that the piedmont glacier lobe developed strong longitudinal crevassing and well-developed ice-marginal pecten during its historical recession. This is recorded by early recessional phase linear push moraines on the shallow, well-drained distal slope of the outermost overridden moraine, indicative of compressive ice flow, followed by later development of inter-related sawtooth moraines, crevasse squeeze ridges and till eskers, indicative of extending ice flow and poorly drained sub-marginal conditions. Hence the glacial geomorphology of the Fláajökull north lobe foreland documents a clear palaeoglaciological signature of a changing process-form regime and allows us to refine the active temperate piedmont lobe landsystem model, specific to forelands characterized by marginal-thickening till wedges and the topographic influence these wedges impose on smaller scale landform production in relation to glacier snout crevasse networks and sub-marginal drainage

conditions. It also clearly demonstrates that the holistic nature of the landsystems mapping approach is a powerful tool in deciphering the palaeoglaciological record.

Software

The dGPS ground control points were processed using the Canadian Spatial Reference System (CSRS) Precise Point Positioning (PPP) tool. The orthophotomap and digital elevation model from UAV-based images were produced in Agisoft Photoscan Professional Edition. The geomorphology for the 1:350 map was prepared in ESRI ArcGIS and edited in Adobe Illustrator. The 1:6,250 scale map was drawn in Adobe Illustrator and the glacier image manipulation was undertaken in Adobe Photoshop.

Figure 4: The early to mid-1990s composite push moraine: a) during formation on the central foreland in 1993; b) cross section through the moraine on the north foreland after its abandonment in 2002, with multiple till units identified (after Evans & Hiemstra 2005); c) view across the moraine on the west foreland in 2014. Note the very steep distal and proximal slopes at this location.

Figure 5: View across the north foreland in 2008, showing the early to mid-1990s composite moraine in the centre foreground and the cross-cutting nature of this and the earlier sawtooth moraines as well as the most recent deglaciated foreland with its complex of overprinted push moraines, crevasse squeeze ridges and till eskers.

Figure 6: The historical Little Ice Age maximum moraines on the southwest margin of the north lobe: a) view across the moraine ridges, showing their bouldery nature; b) stratigraphic exposure through the moraines, showing glacier marginally stacked boulder-rich tills outlined by dashed lines.

Figure 7: View across the recently deglaciated foreland in 2014, showing the details of cross-cutting and merging of crevasse squeeze ridges, sawtooth moraine limbs and frontal lobes, and minor flutings. The dense longitudinal crevasse networks and pecten responsible for these landforms are visible in the glacier snout.

Figure 8: Sinuous diamicton ridge, interpreted as a till esker, on the central foreland.

Figure 9: Views across the recently deglaciated foreland showing the juxtaposition of crevasse squeeze ridges/sawtooth moraines and sparse till eskers, including the area surveyed for the 1:350 scale map: a) ground view with main landforms identified; b) UAV oblique aerial photograph looking south; c) UAV oblique aerial photograph looking north, towards the glacier snout and showing the relationship between landform orientations and pecten.

Figure 10: View across an overridden moraine arc and linear, ice margin-parallel sandur towards the historical Little Ice Age maximum limit. The overridden moraine is outlined by the dashed line and is covered by crevasse squeeze ridges and minor flutings as well as some small recessional push moraines.

Figure 11: Conceptual model for the spatial and temporal development of the landform assemblages on the Fláajökull north lobe foreland, along a simplified topographical cross profile from the historical Little Ice Age limit to the present glacier margin.

FLÁAJÖKULL (NORTH LOBE), ICELAND: Active temperate piedmont lobe glacial landsystem

DAVID J.A. EVANS, MAREK EWERTOWSKI
and CHRIS ORTON
Department of Geography, Durham University, UK

- Glacifluvial deposits, including eskers
- Till and moraines dating to the Little Ice Age (superimposed on overridden moraines)
- Residuum or weathered bedrock, and areas of weathered pre-Little Ice Age till (including areas of aeolian deposits and peat)
- Glacilacustrine deposits
- Made ground
- Paraglacial deposits, small bedrock exposures and debris flow fans and scree
- Bedrock (including small patches of residuum and thin till)
- Glacier ice
- Flutings
- Relict channels
- Lakes and kettle holes
- Rivers
- Major terrace
- Meltwater channels
- Esker
- Moraine ridges
- Crevasse fills and minor till eskers
- Contours (20m intervals)
- Track
- Crop patterns
- Field boundaries
- Location of 1:350 scale map

Based on aerial photography by
Landmælingar Islands, July 1989.

UTM 28N Projection

Contour interval: 20m
(based on ISN 93 datum)
Lambert Projection
